Evidence suggests that thrombosis, endothelial dysfunction and inflammation are strongly associated with coronary artery disease (CAD). Inflammation plays a crucial role in characterizing the formation of atheromatous plaque, as well as its progress. The secretion of proinflammatory cytokines from the vascular endothelium as well as from macrophages induces the production of inflammatory molecules that are measured in the circulation, such as C-reactive protein (CRP), serum amyloid A and fibrinogen. Several studies have focused on fibrinogen, demonstrating a strong association with the presence of CAD, while others failed to show a significant association. Although most of the available data favor the involvement of fibrinogen in CAD, there is still evidence against this hypothesis.

**Link between inflammation and CAD: a role for fibrinogen**

Fibrinogen and its metabolites may lead to endothelial dysfunction through various mechanisms. Several atherosclerotic lesions contain large amounts of fibrin, either in the form of wall thrombus in the intact surface of the plaque or scattered diffusely all over the plaque. This phenomenon is associated with a decrease in fibrinolytic activity and plasminogen concentrations, states that are observed in CAD. It has been found that fibrin (intima) triggers cell proliferation, contributing to cell migration, and bonds fibronectin, which triggers cell migration and adhesion. Fibrinogen and products of its decomposition mediate the transportation of adhesion molecules in the surface of endothelium and their further migration to the intima. The decomposition products located in the inner layer can trigger mitogenesis and synthesis of collagen, attract leukocytes, and enhance permeability as well as vascular tone. In advanced atherosclerotic plaques fibrin participates in the close linkage of low-density lipoprotein (LDL) and lipid accumulation, leading to the creation of the lipid nucleus of atherosclerotic lesions.

In addition, proinflammatory cytokines, such as interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF-α), are produced from the vasculature, adipose tissue and myocardium; these increase the synthesis of nitric oxide (NO) and favor leukocyte migration in the sub-endothelial space. These cytokines also have a further regulatory role, inducing liver synthesis of acute phase proteins, such as fibrinogen, and consequently inflammatory and prothrombotic reactions. Thus, fibrinogen participates in the formation of atherosclerotic plaque during the first stages of CAD, suggesting that it is a causative factor rather than a result.
Evidence supporting the association between fibrinogen and CAD

Early evidence from previous decades pointed to a strong association between fibrinogen levels and CAD manifestation (Table 1).

The Gothenburg Study\textsuperscript{14} reported that plasma fibrinogen levels represent an independent risk factor for myocardial infarction (MI) and stroke in univariate analysis. Similarly, the Framingham study\textsuperscript{15,16} demonstrated that the risk for MI and stroke increased progressively along with fibrinogen levels. The effect of fibrinogen levels on cardiovascular risk was even greater in young individuals and was similar to the effect of known risk factors such as hypertension, diabetes mellitus, and smoking. Another large epidemiological study showed that fibrinogen was not only a strong and independent risk factor for MI and sudden cardiac death in patients with pre-existing CAD, but also had a greater predictive value for future coronary events, compared to von Willebrand factor (vWF) antigen and tissue plasminogen activator antigen.\textsuperscript{17} Novel data from the EPIC-Norfolk study\textsuperscript{18} showed prospectively that fibrinogen levels were significantly higher in patients presenting with fatal or non-fatal coronary heart disease, than in those remaining free of any cardiovascular disease during follow up, while Acevedo et al\textsuperscript{19} reported that fibrinogen was directly associated with the presence of MI and was revealed to be an independent short-term predictor of mortality. One multivariate analysis found an independent association between dual parental and sibling history of MI and plasma fibrinogen levels,\textsuperscript{20} implying that plasma fibrinogen levels may be an inheritable risk factor for CAD in subjects with a strong family history of MI. Interestingly, increased levels of fibrinogen have been correlated with adverse cardiac events after intracoronary stenting, suggesting a potential role of fibrinogen levels in the outcomes following percutaneous coronary interventions.\textsuperscript{21}

Despite the data supporting a role of fibrinogen as a marker of CAD and its manifestations, several studies have investigated the role of fibrinogen as a risk factor or mediator of CAD. Recently, Shojaie et al\textsuperscript{22} and Pineda et al\textsuperscript{23} introduced high levels of fibrinogen as a risk factor for premature CAD in subjects <55 years. A role in subclinical atherosclerosis has been also attributed to this acute phase protein, as higher levels of fibrinogen during young adulthood were positively associated with prevalence of coronary artery calcification and increased carotid intimal-medial thickness in middle age, while the magnitude of the association decreased with aging.\textsuperscript{24} Similarly, fibrinogen and CRP levels were strong predictors of subclinical atherosclerosis (associated with an extension of carotid atherosclerosis) in hypertensive postmenopausal women.\textsuperscript{25} Supporting data had previously shown that fibrinogen is involved in the subclinical phase of extracoronary and coronary atherosclerosis and may add to the atherogenic effect of hyperlipidemia.\textsuperscript{26} Moreover, fibrinogen levels have been found to be independently related to cardiovascular mortality, extent,\textsuperscript{27} as well as the severity of disease.\textsuperscript{28} Moreover, fibrinogen levels were significantly higher in patients presenting with unstable than in those with stable angina, suggesting a role for fibrinogen in the pathophysiology of acute coronary syndromes.\textsuperscript{29}

Conflicting data have been reported by other studies and show no association between fibrinogen levels and CAD (Table 1).\textsuperscript{29-35} However, these results appear surprising, given that the role of fibrinogen in the pathogenesis of CAD has been well evaluated by the majority of the available studies.

The genetic view

There are several gene polymorphisms of fibrinogen chains, recognized during the last decade, which seem to affect fibrinogen levels and consequently the presence of CAD (Table 2). Green et al\textsuperscript{36} showed a significant interaction between smoking status and genotype in determining plasma fibrinogen levels in healthy individuals, providing an independent confirmation of the association between beta(b)-fibrinogen G455A genotype and plasma fibrinogen levels. Similarly, it has been observed that polymorphisms G455A and G845A of the b-chain gene of fibrinogen significantly affect the concentration of the latter.\textsuperscript{37} In particular, the -455G/A polymorphism is one of the most important genetic variables associated with elevated fibrinogen levels in both genders in the general population.\textsuperscript{38} Interestingly, in patients with diabetes mellitus type 2 there was a strong relationship between the -455G/A b-fibrinogen gene polymorphism and the development of CAD.\textsuperscript{39} Additional data have also been reported regarding the same gene polymorphism.\textsuperscript{40} In patients with stable CAD and healthy individuals, the G455A polymorphism increased fibrinogen levels significantly in the wild genotype in patients with CAD; however, no significant effect was observed among healthy individuals.

In addition, fibrinogen levels have been affected...

by other gene polymorphisms, such as A1675G on angiotensin type 2 receptor gene, which was found to affect cardiovascular risk and the severity of atherosclerosis by modifying systemic inflammation (such as fibrinogen), especially in hypertensive males. A significant gene-covariate interaction has also been reported between the factor XIII (fXIII) Val34Leu variant and fibrinogen levels. Importantly, Manilla et al demonstrated that plasma fibrinogen gamma concentration influences the risk of MI, and this association seems to be enhanced by the presence of an elevated total plasma fibrinogen concentration and the fibrinogen gamma chain -9340T and fibrinogen alpha chain -2224G alleles.

Nevertheless, the results are controversial and some studies have failed to point out such correlations between specific gene polymorphisms and plasma fibrinogen levels or CAD development. Sun et al found that fibrinogen levels were related to CAD. However, fibrinogen C148T and G854A polymorphisms were not associated with CAD. Despite the fact that a common mutation (G-455-->A) in the beta-fibrinogen promoter was an independent predictor of plasma fibrinogen, it was not a predictor of ischemic heart disease. Moreover, a significant number of studies failed to ascertain the association between polymorphisms in the fibrinogen gene and cardiovascular risk. Novel data reported the absence of an association between the b-chain fibrinogen gene -148C/T polymorphism, while there is susceptibility to the risk of CAD for the G455A polymorphism. Similarly, Kardys et al showed that specific fibrinogen gene haplotypes were not associated with coronary events.

Conclusions

Fibrinogen represents an inflammatory marker that appears to be implicated in the pathophysiology and prognosis of CAD. Its presence contributes to the formation of atheromatous plaque, while it contributes to the development of acute coronary syndromes via its interaction with other inflammatory substances, endothelium and thrombotic molecules. The vast majority of studies focusing on the association between fibrinogen levels and CAD, even gene-related, demonstrated a positive correlation, while others failed to show any correlation. In addition, several gene polymorphisms of fibrinogen chains are associated with cardiovascular events and fibrinogen levels. Although fibrinogen is used widely in clinical practice and epidemiological studies have evaluated its role in CAD, there are still aspects that need further investigation. Thus, many more large scale studies are required to evaluate the association of fibrinogen with advanced atherosclerosis.
